Animal model of methylphenidate’s long-term memory-enhancing effects

Stephanie A. Carmack,1 Kristin K. Howell,1 Kleou Rasaei,1 Emilie T. Reas,2 and Stephan G. Anagnostaras1,2,3

Methylphenidate (MPH), introduced more than 60 years ago, accounts for two-thirds of current prescriptions for attention deficit hyperactivity disorder (ADHD). Although many studies have modeled MPH’s effect on executive function, almost none have directly modeled its effect on long-term memory (LTM), even though improvement in LTM is a critical target of therapeutic intervention in ADHD. We examined the effects of a wide range of doses of MPH (0.01–10 mg/kg, i.p.) on Pavlovian fear learning, a leading model of memory. MPH’s effects were then compared to those of atomoxetine (0.1–10 mg/kg, i.p.), bupropion (0.5–20 mg/kg, i.p.), cilazapram (0.01–10 mg/kg, i.p.). At low, clinically relevant doses, MPH enhanced fear memory; at high doses it impaired memory. MPH’s memory-enhancing effects were not confounded by its effects on locomotion or anxiety. Further, MPH-induced memory enhancement seemed to require both dopamine and norepinephrine transporter inhibition. Finally, the additive potential of MPH (1 mg/kg and 10 mg/kg) was compared to those of two other psychostimulants, amphetamine (0.005 mg/kg and 1.5 mg/kg) and cocaine (0.15 mg/kg and 15 mg/kg), using a conditioned place preference and behavioral sensitization paradigm. We found that memory-enhancing effects of psychostimulants observed at low doses are readily dissociable from their reinforcing and locomotor activating effects at high doses. Together, our data suggest that fear conditioning will be an especially fruitful platform for modeling the effects of psychostimulants on LTM in drug development.

[Supplemental material is available for this article.]
We also assessed whether MPH's procognitive and reinforcing effects are dissociable using a conditioned place preference (CPP) and behavioral sensitization paradigm. Behavioral sensitization is a progressive increase in response following repeated administration and models the transition from casual to compulsive use (Robinson and Berridge 1993, 2003). Place preference is the preference for a context previously paired with a drug and is a model of drug seeking. We compared MPH's reinforcing ability with those of amphetamine (AMPH) and cocaine (COC).

In all, we found that memory-enhancing effects of psychostimulants at low doses are readily dissociable from their reinforcing and locomotor activating effects at high doses. We further found that MPH was neither anxiogenic nor anxiolytic. We conclude that MPH's ability to enhance long-term memory appears to be due to a combination of DAT and NET inhibition. We consider whether these results support a direct effect on associativity and memory, rather than as incidental to improved executive function (Barkley 1997).

**Results**

**MPH dose-effect curve on fear conditioning**

MPH's (0.01–10 mg/kg, i.p.) effects on long-term memory were investigated using Pavlovian fear conditioning. MPH dose-dependently increased locomotor activity during the training baseline ($F_{4,70} = 11.87$, $P < 0.0001$) (Fig. 1A). Only mice given 10 mg/kg MPH showed significantly more activity than the saline control group (PLSD, $P < 0.0001$; all other $P$ values $>0.3$). The 2-sec shock elicited a large increase in velocity, known as the unconditioned response, which did not significantly differ between groups ($F_{4,70} = 0.79$, $P = 0.54$) (Fig. 1B).

MPH dose-dependently modulated freezing during the first 5 min of training (on drug data not depicted) ($F_{4,66} = 6.03$, $P < 0.0001$). Compared to saline controls (0 mg/kg), 0.01 mg/kg enhanced freezing ($P < 0.005$), 10 mg/kg decreased freezing ($P < 0.04$), and 0.1 and 1 mg/kg MPH produced no significant effect ($P$ values $>0.6$).

There were significant overall group differences in freezing during the immediate memory test ($F_{4,70} = 6.74$, $P < 0.0001$) (data not graphed). Mice given 10 mg/kg froze ($0.4 \pm 0.2\%$, significantly less than saline controls ($22.2 \pm 3.8\%$, $P < 0.0001$). However, 10 mg/kg MPH’s ability to stimulate activity likely influenced freezing (Fig. 1A). No other doses affected immediate memory (0.01, 28.9 $\pm 4.2\%$; 0.1, 20.1 $\pm 4.2\%$; 1, 23.4 $\pm 4.5\%$; $P$ values $>0.2$).

To determine if MPH influenced long-term contextual memory, mice were returned to the conditioning context 7 d later off drug. Pretraining MPH dose-dependently modulated memory ($F_{4,70} = 5.46$, $P = 0.001$) (Fig. 1C). Compared to saline controls, 1 mg/kg enhanced memory ($P = 0.027$), 10 mg/kg MPH reduced memory ($P = 0.012$), and 0.01 and 0.1 mg/kg MPH failed to influence memory to the context ($P$ values $>0.5$).

Tone memory was assessed 24 h later (Fig. 1D). Baseline freezing was very low and did not differ between groups (not depicted; 0 mg/kg, 4.68 $\pm 1.8\%$; 0.01 mg/kg, 8.1 $\pm 2.1\%$; 0.1 mg/kg, 14.3 $\pm 5.3\%$; 1 mg/kg, 9.2 $\pm 4.0\%$; 10 mg/kg, 3.5 $\pm 0.9\%$; $F_{4,66} = 1.89$, $P > 0.10$). Again, MPH dose-dependently modulated memory ($F_{4,70} = 2.78$, $P = 0.034$). Both 0.01 and 1 mg/kg MPH dramatically enhanced memory relative to saline controls ($P$ values $<0.05$). No other doses influenced freezing to the tone ($P$ values $>0.10$).

Overall, we were able to model MPH’s dose-dependent memory-enhancing effects using Pavlovian fear conditioning. Clinically relevant doses of MPH given pretreatment enhanced long-term contextual and tone memory. In contrast, a high dose of MPH impaired contextual memory.

**MPH and elevated plus maze**

MPH may have modulated anxiety rather than memory acquisition. To control for this possibility, we investigated the effect of 0, 1, and 10 mg/kg MPH on the elevated plus maze. MPH had no effect on the percent of total time spent in the open vs. enclosed
Methylphenidate enhances long-term memory

We selected the two doses of MPH—1 and 10 mg/kg—that modulated memory (Fig. 1D) and investigated their addictive potential.

Figure 2A depicts locomotor activity (distance traveled) on training day 1 on the Paired side. Similar to our observations in fear conditioning (Fig. 1A), the acute response to various doses of MPH were significantly different ($F_{(2,36)} = 9.83$, $P < 0.0001$). Compared to saline controls, 10 mg/kg increased ($P < 0.0001$) and 1 mg/kg MPH had no effect on locomotor activity ($P > 0.7$).

Figure 2B shows locomotor activity across days of training on the Paired side. Significant group differences were observed ($F_{(2,36)} = 30.0$, $P < 0.0001$). Mice receiving 10 mg/kg MPH showed greater locomotor activity than mice receiving saline or 1 mg/kg ($P < 0.0001$), which did not differ from each other ($P > 0.5$). Sensitization was quantified as the difference in average locomotor response from days 1–7. Only the mice receiving 10 mg/kg MPH exhibited sensitization. Neither the saline control nor the 1 mg/kg MPH groups showed sensitization, and these groups did not differ.

Figure 2B shows stereotypy during training on the Paired side. Significant group differences were observed ($F_{(2,36)} = 63.0$, $P < 0.0001$). In terms of average response, mice receiving 10 mg/kg MPH showed greater stereotypic activity than mice receiving saline or 1 mg/kg ($P < 0.0001$), which did not differ from each other ($P > 0.7$). As with locomotor activity, there were significant group differences in sensitization ($F_{(2,36)} = 23.0$, $P < 0.0001$) (Fig. 2E). Only the mice receiving 10 mg/kg MPH sensitized ($P < 0.0001$). No other groups showed sensitization ($P > 0.2$).

To test CPP, mice were returned off drug with free access to both sides of the apparatus. Preference was measured as the time spent and distance traveled on the Paired vs. Unpaired side. There were significant group differences in both time spent ($F_{(2,36)} = 17.1$, $P < 0.0001$) (Fig. 2F) and distance traveled ($F_{(2,36)} = 8.87$, $P < 0.001$) (Fig. 2G). Mice given 10 mg/kg MPH showed substantial CPP (time spent, one sample two-tailed t-test against hypothesized $μ = 0$, $t_{(12)} = 8.49$, $P < 0.001$; distance traveled, $t_{(12)} = 6.14$, $P < 0.0001$) and greater preference for the Paired side than the other groups. Mice that received 1 mg/kg MPH showed a very small, but significant preference for the drug-paired side. The saline control group did not show any preference.

To further explore sensitization, mice were challenged with low MPH (1 mg/kg) and then high MPH (10 mg/kg) on the Paired side (Fig. 3). There were no overall group differences in locomotor activity ($P = 0.112$) (Fig. 3A, left) following the low MPH challenge, but there were significant group differences in stereotypic counts ($F_{(2,36)} = 7.95$, $P = 0.001$) (Fig. 3B, left). The group...
trained with 10 mg/kg MPH showed significantly more stereotyped activity than both the saline control group and the group trained with 1 mg/kg MPH (P values < 0.01), which did not differ from each other (P > 0.2). Only the group trained with 10 mg/kg MPH group showed evidence of a sensitized response to the low MPH challenge.

When challenged with a high dose of MPH (10 mg/kg, i.p.), there were significant differences in both locomotor (F(2,36) = 4.82, P = 0.014) (Fig. 3A) and stereotypic activity (Fig. 3B, right; F(2,36) = 7.83, P = 0.001). The group trained with 1 mg/kg MPH exhibited some latent sensitization of locomotor activity and had significantly greater locomotor activity than the saline control and 10 mg/kg MPH groups (P values < 0.03) (Fig. 3A, right). Surprisingly, these groups did not differ in locomotor response (P = 0.55). This finding appears to be driven by the 10 mg/kg MPH group's transition into stereotyped behavior. Indeed, the 10 mg/kg MPH group showed significantly greater stereotyped behavior than the other groups (P values < 0.05), which did not differ (P > 0.05) (Fig. 3B, right). Both groups trained with MPH showed some sensitization in response to a high MPH challenge injection.

In sum, 1 mg/kg MPH had very minimal addictive potential. Repeated administration of 1 mg/kg MPH did not lead to the development of sensitization. However, challenge with a high dose (10 mg/kg MPH) injection induced some latent locomotor sensitization and there was very slight place preference. In contrast, repeated administration of 10 mg/kg MPH induced strong behavioral sensitization and CPP.

**AMPH- and COC-induced CPP and sensitization**

We extend these dissociable behavioral findings with MPH to two other psychostimulants, AMPH and COC. Low memory-enhancing doses of AMPH (0.005 mg/kg) (Wood and Anagnostaras 2009) and COC (0.15 mg/kg) (Wood et al. 2007) failed to induce behavioral sensitization or CPP. In contrast, high, memory-impairing doses of AMPH (1.5 mg/kg) and COC (15 mg/kg) had significant addictive potential (Fig. 4; see Supplemental Results for details).

**Figure 3.** MPH-induced behavioral sensitization. (A) Sensitization of locomotor activity. No group differences in distance traveled were observed following a challenge injection of 1 mg/kg MPH (left). In contrast, following a challenge injection of 10 mg/kg MPH, the group trained with 1 mg/kg MPH showed significantly more locomotor activity than the groups previously given saline or 10 mg/kg MPH, which did not differ from each other (right). (B) Sensitization of stereotyped activity. The group trained with 10 mg/kg MPH showed significantly more stereotyped activity in response to a 1 mg/kg MPH challenge injection than both the saline control group and the group trained with 1 mg/kg MPH, which did not differ from one another (left). When challenged with a high dose of MPH (10 mg/kg), the group trained with 10 mg/kg MPH had significantly greater stereotopic counts than the other groups, which did not differ from one another (right). The transition to stereotyped behavior observed only in the group trained with 10 mg/kg MPH explains their lack of locomotor sensitization during the high dose MPH challenge test. Each point represents the mean ± 1 standard error.

**Figure 4.** AMPH and COC-induced addiction-related behaviors. (A) Locomotor activity as an average of the seven training sessions on the drug-paired side. Mice receiving 1.5 mg/kg AMPH showed greater locomotor activity than mice receiving saline or 0.005 mg/kg AMPH, which did not differ from each other. (B) Development of AMPH-induced locomotor sensitization. Sensitization was quantified as the difference in average locomotor response from days 1–7. Only the mice receiving 1.5 mg/kg AMPH exhibited sensitization. Neither the saline control nor the 0.005 mg/kg AMPH groups showed sensitization. (C) AMPH-induced conditioned place preference. Preference was measured as the difference between the percent of time spent on the Paired side vs. the Unpaired side; positive values indicate preference for the Paired side. Mice that received 1.5 mg/kg AMPH showed substantial place preference for Paired side. The saline control group and 0.005 mg/kg AMPH groups did not show any preference. (D) Locomotor activity as an average of each day across the seven training sessions on the drug-paired side. Mice receiving 15 mg/kg COC showed greater locomotor activity than mice receiving saline or 0.15 mg/kg COC, which did not differ from each other. (E) Development of COC-induced locomotor sensitization. Only the mice receiving 15 mg/kg AMPH sensitized. Neither the saline control nor the 0.15 mg/kg COC group sensitized. (F) COC-induced conditioned place preference. Mice that received 15 mg/kg COC showed substantial place preference and greater preference for the Paired side than the other groups. The saline control group and 0.15 mg/kg COC groups did not show any preference. Each point represents the mean ± 1 standard error.
Neurobiological mechanisms of MPH’s dose-dependent behavioral effects

To investigate the neurobiological mechanisms that underlie MPH’s dose-dependent dissociable behavioral effects, we examined the selective transporter inhibitors ATM, BUP, and CIT on Fear memory (Supplemental Fig. S1A–I); for a detailed description, see Supplemental Material. Briefly, across the range of doses tested, ATM, BUP, and CIT failed to enhance LTM. In contrast, high doses of BPN and CIT impaired LTM (Supplemental Fig. S1E,H,I). Taken together with previous work in our lab demonstrating that low doses of AMPH and COC enhance LTM (Wood et al. 2007; Wood and Anagnostaras 2009), it is interesting to speculate that psychostimulants’ ability to enhance LTM acquisition may be related to binding multiple transporter targets, in particular NET and DAT. In Table 1 our results are compared to published affinity studies (Wong et al. 1982; Richelson and Pfennig 1984; Forest Laboratories 2011; GlaxoSmithKline 2013). Within the realm of drugs often prescribed for ADHD, drugs that are highly selective for a single transporter (ATM, CIT) failed to enhance LTM. In contrast, low doses of combined high affinity DAT and NET inhibitors AMPH, COC, and MPH enhanced memory without evidence of reinforcement. At high doses, however, many of the drugs impaired LTM (MPH, AMPH, COC, BUP, and CIT), produced locomotor hyperactivity (MPH, AMPH, COC), and showed evidence of reinforcement and addiction (AMPH, COC, MPH).

Discussion

More than 65 years after its introduction, MPH is the first-line treatment for ADHD (Spencer et al. 1996; Barkley 1998). MPH can have serious side effects, however, including growth retardation, nausea, insomnia, anxiety, tics, and cardiovascular risk (McNeil Pediatrics 2008), suggesting need for further development of psychostimulants. Though progress has been made in ADHD drug delivery, recently approved therapeutics, such as atomoxetine and guanfacine, are inferior in clinical efficacy to MPH or AMPH, despite their ability to reduce inattention and impulsivity (Wigal et al. 2005; Faraone et al. 2007; Newcorn et al. 2008). Most clinical efficacy studies only report inattention/hyperactivity–impulsivity measures (ADHD IV) (Dittmann et al. 2013) and clinical global impression (CGI) (Setyawan et al. 2013). These studies do not assess efficacy in improving LTM. Rather, they focus on improvements in problem classroom behaviors even though a growing body of evidence shows an impairment of LTM in ADHD (Rhodes et al. 2012).

MPH’s clinical efficacy is generally modeled using attention or cognitive control tasks, such as attentional set-shift, stop-signal, and five-choice serial reaction time (Puuimala et al. 1996; Robbins 2002; Arnsten and Dudley 2005; Eagle et al. 2007; Berridge et al. 2012; Humby et al. 2013). However, these models do not assess LTM and are difficult to implement in high throughput drug development as they are complex, sometimes require extensive training, and often are in monkeys. Drug development will benefit from the addition of this simple, efficient mouse model of MPH’s effects on LTM because of cost, the widespread use of mice preclinically, and the widely available genetic tools in mice.

At 1 mg/kg, MPH enhanced the acquisition of both contextual and tone memory. Even lower doses (0.01–0.1 mg/kg) dramatically enhanced tone memory. This finding is consistent with previous research showing that low doses of AMPH, modafinil, and COC enhance fear memory (Wood et al. 2007; Shuman et al. 2009; Wood and Anagnostaras 2009). Further, MPH modulates fear memory independent of its effects on locomotor activity or anxiety.

Pavlovian fear conditioning has become especially useful as an experimental model in psychiatric research because of its simplicity (LeDoux 1998; Maren 2008; Mahan and Ressler 2012):

aPublished Ki values are shown for methylphenidate, amphetamine, cocaine, bupropion, citalopram (Richelson and Pfennig 1984), and atomoxetine (Wong et al. 1982) in the rat brain. Please note low Ki values indicate high affinity.
b↑(↑) The drug elevates locomotor activity at the specified dose; (↓) the drug decreases locomotor activity; (–) no effect. c↑(↑) The drug increases addictive potential at the specified dose; (–) no known addictive potential; (?) the drug effect is not known. d↑(↑) The drug enhances memory at the specified dose; (↓) the drug impairs memory; (–) no effect. eMethylphenidate’s locomotor and reinforcing effects are depicted in Figures 4A–C; its effect on memory is previously published (Fig. 3 in Wood and Anagnostaras 2009). fCocaine’s locomotor and reinforcing effects are depicted in Figure 4D–F; its effect on memory is previously published (Fig. 3 in Wood et al. 2007). gAtomoxetine’s locomotor and reinforcing effects are shown in Supplemental Figures S1A and S2; its effects on memory are shown in Supplemental Figure S1, B and C. hBupropion’s locomotor and reinforcing effects are reported in Wellbutrin’s FDA approved labeling (GlaxoSmithKline 2013); its effects on memory are shown in Supplemental Figure S1, F and I. iCitalopram’s locomotor and reinforcing effects are reported in Celexa’s FDA approved labeling (Forest Laboratories 2011); its effects on memory are shown in Supplemental Figure S1, H and I.
Methylphenidate enhances long-term memory

A single tone–shock pairing can result in a long-lasting memory (Fig. 1). Additionally, its established neural circuitry is similar between rodents and humans (LeDoux 1998; Delgado et al. 2006). MPH, a high affinity DAT and NET inhibitor (Han and Gu 2006), likely enhances memory acquisition by increasing monoamine neurotransmission (Kuczenski and Segal 1997, 2002; Lazzaro et al. 2010; de Oliveira et al. 2011; Johansen et al. 2011). We tested CIT, ATM, and BPN on fear learning to investigate the consequences of selectively blocking SERT, NET, and DAT. Reviewing these very generally, one is left with the impression that considerable affinity for both NET and DAT may be required for the cognitive enhancing effects of psychostimulants (Table 1; Wong et al. 1982; Richelson and Penning 1984; Forest Laboratories 2011; GlaxoSmithKline 2013).

MPH's effects on memory acquisition are often construed to be the exclusive result of improved attention or executive control (Barkley 1997). This interpretation is difficult to reconcile with our observation that MPH dramatically enhances long-term tone memory (Fig. 1D). The attentional demands in tone fear conditioning are modest at best; a very loud tone is followed by an even more attention-grabbing, inescapable foot shock. Furthermore, although working memory is heavily conflated with executive control, decades of evidence suggest that the core neurobiology of LTM is distinct from that of executive control (Morgan and LeDoux 1995; Braver et al. 2001). This suggests that MPH may also directly influence core associative mechanisms such as long-term potentiation (LTP).

Substantial evidence does exist that MPH acts on cellular substrates implicated in LTM; for example, MPH enhances long-term potentiation and depression (Dommett et al. 2008; Tye et al. 2010). Recently, acute administration of MPH in rats has been shown to facilitate plasticity in the amygdala via an increase in AMPA receptor-mediated currents following a cue–reward learning task (Tye et al. 2010). MPH also increases hippocampal norepinephrine in vivo (Kuczenski and Segal 2002) and such changes are known to influence synaptic plasticity (Akirav and Richter-Levin 2002). Thus, the potential that MPH directly improves learning or associative directly warrants further investigation. Ultimately, improved classroom learning will be demonstrated by improvements in LTM, such as on exams.

We further demonstrate that MPH's memory-enhancing effect at low doses is dissociable from its reinforcing effects induced by high doses. Most animal studies have used doses 2–40 times higher than the clinically relevant dose in an effort to model addiction (Gainetdinov et al. 1999; Kuczenski and Segal 2002; Abraham et al. 2012). We have advocated using a one-to-one dosing scheme unless specific evidence warrants using a different dose in mice (Wood et al. 2007; Shuman et al. 2009; Wood and Anagnostaras 2009). No evidence suggests that appropriate rodent dosing should be 40 times higher than human dosing. MPH is prescribed around 0.5–1 mg/kg, available in a variety of time-released preparations, but is typically dosing should be 40 times higher than human dosing. MPH is (Anagnostaras 2009). No evidence suggests that appropriate rodent dose in mice (Wood et al. 2007; Shuman et al. 2009; Wood and Anagnostaras 2012). We have advocated using a one-to-one dosing scheme unless specific evidence warrants using a different dose in mice (Wood et al. 2007; Shuman et al. 2009; Wood and Anagnostaras 2009). No evidence suggests that appropriate rodent dosing should be 40 times higher than human dosing. MPH is available in a variety of time-released preparations, but is typically prescribed around 0.5–1 mg/kg, and is not meant to exceed 2 mg/kg/day (McNeil Pediatrics 2008). The memory-enhancing doses that we observed (0.01–1 mg/kg) accord well with and are on the same order of magnitude as prescribed doses.

The memory-enhancing dose (1 mg/kg MPH) showed little evidence of reinforcement. In contrast, 10 mg/kg MPH not only produced sensitization, place preference, and a marked stimulating effect, but it also impaired memory. This dissociation is supported by our observation that memory-enhancing doses of AMPH (0.005 mg/kg) and COC (1.5 mg/kg) also showed little evidence of reinforcement, while high, addictive, doses impaired memory (Fig. 4). Together, these results substantiate the view that psychostimulant dosage explains the “paradox” of cognitive enhancements in patient populations and cognitive deficits in addicts (Rapport et al. 1980; Ellinwood et al. 1998; Rapoport and Inoff-Germain 2002; Berridge and Devilbiss 2011; Wood et al. 2013). As dosage dramatically dissociates psychostimulants’ pro-cognitive and reinforcing effects, it is likely that one can develop an MPH-like drug, which retains all of MPH’s pro-cognitive effects, but lacks any reinforcing effects. Though, to date, such efforts have been limited.

Overall, we found a clear long-term enhancement of memory by MPH at doses similar to those prescribed for ADHD; these memory-enhancing effects were not confounded by effects on locomotion or anxiety and were readily dissociable from the reinforcing effects seen at high doses. Together, our data suggest that fear conditioning will be an especially fruitful platform for modeling the effects of psychostimulants on LTM in drug development.

Materials and Methods

Subjects

We used 380 hybrid CS7BL/6Jx129S1/SvImJ (Jackson Labs) group-housed mice, at least 10 wk old before testing. The vivarium was on a 14:10-h light–dark schedule and testing occurred during the light phase. All procedures were approved by the UCSD IACUC and compliant with the NRC Guide.

Drugs

Dosing was by salt weight and the vehicle was always 0.9% saline. Methylphenidate HCl (Sigma-Aldrich) was given in 0.01, 0.1, 1, or 10 mg/kg. Atomoxetine HCl (Tata) was given in 0.01, 0.5, 1, or 10 mg/kg. Bupropion HCl (Bioimol) was given in 0.5, 5, 10, or 20 mg/kg. Citalopram HBr (Enzo) was given in 0.01, 0.1, 1, or 10 mg/kg. L-Fluoxetine HCl (Sigma) was given in 0.005 or 1.5 mg/kg. Cocaine HCl (Sigma) was given in 0.15 or 15 mg/kg. All injections were given intraperitoneally (i.p.), 10 ml/kg.

Fear conditioning

Eight mice were tested concurrently in individual conditioning chambers. The VideoFreeze system (Med Associates) was used as described previously (Anagnostaras et al. 2010; Carmack et al. 2010, 2013); see Supplemental Methods for details of all drugs tested. For MPH experiments mice were injected 30 min before training. Mice were randomly assigned to groups by dose of MPH administered: 0 (saline control, n = 17), 0.01 (n = 14), 0.1 (n = 14), 1 (n = 12), or 10 mg/kg (n = 14).

Training began with a 3-min baseline, followed by one tone–shock pairing, consisting of a 30-sec tone (2.8 kHz, 85 dBA) that co-terminated with a 2-sec scrambled, AC foot shock (0.75 mA, RMS). Mice were in the chambers for a total of 10 min (Wood and Anagnostaras 2011). Freezing behavior and locomotor activity were recorded (Anagnostaras et al. 2000; Carmack et al. 2010). Mice were returned to the training context, without drug, 7 d later. Freezing was scored for 5 min to measure context fear. Mice were placed in an alternate context 24 h later, also off drug, to measure tone fear. The training context was altered for tone testing: white acrylic sheets were placed over the grid floors and a black plastic, triangular tepee was placed inside each box. Only near-infrared light was used, creating a dark environment. The chambers were cleaned and scented with a 5% vinegar solution. Tone testing consisted of a 2-min baseline, followed by a 3-min tone (2.8 kHz, 85 dBA).

Elevated plus maze

The plus maze (MED Associates) had two open and two enclosed arms (6.5 cm × 36 cm each) joined at a center hub (6.5 cm × 6.5 cm) elevated 74 cm from the ground. Testing lasted 5 min in dim light. The floor of the maze had near infrared backlighting invisible to the mice to provide video contrast. Mice were tracked using a camera and video tracking software (Panlab Smart 3.0, Harvard Apparatus). Mice were given 0 (saline control, n = 8),
1 (n = 8), or 10 mg/kg MPH (n = 8) 30 min prior to testing. Time spent, distance traveled, and transitions (head and shoulder entries) between each section were recorded.

**Conditioned place preference (CPP) and behavioral sensitization**

Eight mice were tested concurrently in individual CPP chambers (43 × 43 × 31 cm, Med Associates) as previously described (Carmack et al. 2013). Each chamber consisted of two distinct (visual, tactile, and odor cues) sides bisected by an opaque wall with a removable insert. Activity Monitor software (Med Associates) used infrared beams to detect mouse position and to derive locomotor activity (distance) and stereotypy (counts). Mice were habituated to the apparatus for 30 min per side per day for 2 d prior to training.

On each of seven daily CPP training sessions, mice were placed into each side of the apparatus for 15 min per side per day. All mice were first given saline prior to placement into the first side (Unpaired). Then, all mice were given drug prior to placement into the second side (Paired). The compartments were counterbalanced. For MPH experiments, mice were assigned to one of three drug groups (n = 13/group): 0 (saline control), 1 (low dose), or 10 (high dose) mg/kg MPH. These doses of MPH maximally enhanced and impaired fear memory in the fear conditioning experiment (Fig. 1C).

Twenty-four hours after the final training session, mice were tested off drug for CPP. The insert was removed and subjects were allowed access to both sides of the chamber for 15 min.

To measure the development of sensitization, distance traveled and stereotyped activity were recorded during training on the Paired side. Development of sensitization was calculated as the difference between day 1 (acute) and day 7 (sensitized) response. Additionally, all mice received two challenge tests: one with a low dose (1 mg/kg MPH) 48 h after training, and one with a high dose (10 mg/kg MPH) 72 h after training. For both tests, all mice were injected with drug and immediately placed into the Paired side for 45 min.

AMPH’s and COC’s ability to induce CPP and sensitization at low (0.005 and 0.15 mg/kg) and high doses (1.5 and 15 mg/kg) were also investigated using the above protocol. These doses maximally enhanced or impaired memory in previously published work (Wood et al. 2007; Wood and Anagnostaras 2009); see Supplemental Methods for more details.

**Statistical analyses**

Data were analyzed using multivariate or univariate analyses of variance (ANOVA). Post-hoc comparisons were performed following significant omnibus comparisons using Fisher’s protected least significant difference tests. The level of significance was P ≤ 0.05. We found no evidence of sex-related differences in any measures (P values >0.2), so male and female data were collapsed.

**Acknowledgments**

We gratefully acknowledge Leila Davis, Alexandra Cifelli, Monette Leyva, Vanessa Wu, Sarah D’Angelo, Carina Block, and Erin McNally for technical assistance. We also thank Antonio Mejia, Roy Jungh and Gilberto Sanchez for excellent animal care. We thank Jordan Comins and Liz Harrison for helpful comments on an earlier version of this manuscript. These studies were supported by NIH grant DA020041 (S.G.A.), Hellman Fellowship (S.G.A.), NSF Graduate Research Fellowship (K.K.H.), and UCSF Chancellor’s Interdisciplinary Collaborators Grant (S.A.C., E.T.R.).
